**ABSTRACT**

In this work, we adopt an information theoretic approach - the Information Bottleneck method - to extract the relevant modulation frequencies across both dimensions of a spectrogram, for speech / non-speech discrimination (music, animal vocalizations, environmental noises). A compact representation is built for each sound ensemble, consisting of the maximally informative features. We demonstrate the effectiveness of a simple thresholding classifier which is based on the similarity of a sound to each characteristic modulation spectrum. When we assess the performance of the classification system at various SNR conditions using F-measure, results are equally good to a recently proposed method based on the same features but having significantly greater complexity.

1. INTRODUCTION

Robust automatic audio classification and segmentation in real world conditions is a research area of great interest with applications in many areas of speech technology like speech and speaker recognition, and in multimedia processing for automatic labeling and extraction of semantic information. It has been argued that the statistical analysis of natural sounds - including animal vocalizations and speech - could reveal the neural basis of acoustical perception. Insights in the auditory processing could be exploited in the speech and audio engineering applications listed above.

It is worth to note that all natural sounds are characterized by slow spectral and temporal modulations. However, auditory neurons seem to be able to discriminate relevant from irrelevant sound ensembles, by tuning to the auditory features that differ across them. Speech is characterized by joint spectro-temporal energy modulations; oscillations in power across spectral and temporal axes in spectrogram reflect formant peaks and their transitions, spectral edges, and fast amplitude modulations at onsets-offsets. Of particular relevance to speech intelligibility are the slow temporal modulations (few Hz) which correspond to the phonetic and syllabic rates of speech.

Spectrogram modulations at multiple resolutions can be estimated using the auditory model of Shamma et al. The model has been successfully applied in the assessment of speech intelligibility, the discrimination of speech from non-speech, and other simulations of psychoacoustical phenomena. These auditory representations of sounds are highly redundant, which might yield an advantage in the presence of noise and uncertainty since this adds robustness. However, the *curse of dimensionality* states that the number of training examples required to achieve a fixed upper bound on a classifier generalization error, grows exponentially with the feature dimensions. It is crucial, then, to reduce dimensionality in such a way that the remaining set of features still captures enough information about a class.

A generalization of the Singular Value Decomposition (SVD) to higher - order tensors, Higher Order SVD (HOSVD), has been applied to the auditory features in. HOSVD allows to remove redundancies from each subspace separately, permitting to choose the number of dimensions to keep per subspace. Application of HOSVD to tensors is quite similar to principal component analysis (PCA) of vectors. These techniques yield the dimensions which best represent the data, but might be suboptimal for data classification. An alternative method of dimensionality reduction is the Information Bottleneck Method (IB) proposed by Tishby et al. The IB method enables to construct a compact representation for each class, maintaining its most relevant features. In, a general speech-oriented implementation of IB has been presented, using Mel frequency cepstral coefficients (MFCC). According to the recognition task, a small subset of MFCCs was selected which preserved high mutual information about the target variable.

In this paper, we estimate the power distribution in the modulation spectrum of speech signals, and compare it to the modulation statistics of other sounds. The auditory model of Shamma et al. is the basis for these estimations. Using IB method, we show that an efficient dimensionality reduction is achieved while modulation frequencies which distinguish speech from other sounds are preserved (and estimated). A simple thresholding classifier is proposed, which is based on the similarity of sounds to the compact modulation spectra. Its performance is compared to the system of which uses HOSVD before classification with Support vector machines (SVMs). According to F-measure, our system is almost equivalent to the system of, in spite of its significantly lower complexity. For evaluation purposes, we have also implemented another system based on MFCCs, Zero Crossing Rates (ZCRs) and SVMs classifiers. This served as a reference system to show the robustness of auditory features to various noise conditions.

The auditory model of Shamma et al. is presented in brief in Section. In Section we describe the information theoretic principle, the sequential information bottleneck procedure applied to auditory features and the thresholding classifier. In Section we compare the performance of the proposed system, the system in and the reference system (MFCCs and ZCRs) on a benchmark set using F-measure at various SNR conditions.
2. COMPUTATIONAL AUDITORY MODEL

Early stages of the model estimate an enhanced spectrum of sounds, while at later stages spectrum analysis occurs: fast and slow modulation patterns are detected by arrays of filters centered at different frequencies, with Spectro-Temporal Response Functions (STRFs) resembling the receptive fields of auditory midbrain neurons [3]. These have the form of a spectro-temporal Gabor function, selective for specific frequency sweeps, bandwidth, etc., performing actually a multiresolution wavelet analysis of the spectrogram [4]. The auditory based features are collected from an audio signal in a frame-per-frame scheme. For each time frame, the auditory representation is calculated on a range of frequencies, scales (of spectral resolution) and rates (temporal resolution). In this study, the scales are set to \(s = [0.5, 1, 2, 4, 8]\) cyc/dec, the rates (positive and negative) to \(r = [1, 2, 4, 8, 16, 32]\) Hz. The extracted information is averaged over time, therefore resulting in a 3-dimensional array, or third-order tensor. The dimensionality of this set covers 128 logarithmic frequency bands \(\times 5\) scales \(\times 12\) rates. We have used the "NSL Tools" MATLAB package (courtesy of the Neural Systems Laboratory, University of Maryland, College Park, downloadable from http://www.isr.umd.edu/CAAR/pubs.html).

3. INFORMATION BOTTLENECK METHOD

In Rate Distortion theory a quantitative measure for the quality of a compact representation is provided by a distortion function. In general, definition of this function depends on the application: in speech processing, the relevant acoustic distortion measure is rather unknown, since it is a complex function of perceptual and linguistic variables [11]. IB method provides an information theoretic formulation and solution to the tradeoff between compactness and quality of a signal's representation [10][12][11]. In the supervised learning framework, features are regarded as relevant if they provide information about a target. IB method assumes that this additional variable \(Y\) (the target) is available. In the case of speech processing systems, the available tagging \(Y\) of the audio signal (as speech / non speech, speakers or phonemes) guides the selection of features during training. The relevance of information in the representation of an audio signal, denoted by \(X\), is defined as the amount of information it holds about the other variable \(Y\). If we have an estimate of their joint distribution \(p(x,y)\), a natural measure for the amount of relevant information in \(X\) about \(Y\) is given by Shannon’s mutual information between these two variables:

\[
I(X;Y) = \sum_{x,y} p(x,y) \log \frac{p(x,y)}{p(x)p(y)}
\]  

(1)

where the discrete random variables \(x \in X\) and \(y \in Y\) are distributed according to \(p(x)\), and \(p(y)\), respectively. Further, let \(\tilde{x}\) \(\in \tilde{X}\) be another random variable which denotes the compressed representation of \(x\); \(\tilde{x}\) is transformed to \(\tilde{x}\) by a (stochastic) mapping \(p(\tilde{x}|x)\). Our aim is to find an \(\tilde{X}\) that compresses \(X\) through minimization of \(I(\tilde{X};X)\), i.e. the mutual information between the compressed and the original variable. At the same time, the compression of the resulting representation \(\tilde{X}\) should be minimal under the constraint that the relevant information in \(\tilde{X}\) about \(Y\), \(I(\tilde{X};Y)\) stays above a certain level. This constrained optimization problem can be expressed via Lagrange multipliers, with the minimization of the IB variational functional:

\[
\mathcal{L} \{ p(\tilde{x}|x) \} = I(\tilde{X};X) - \beta I(\tilde{X};Y)
\]  

(2)

where \(\beta\), the positive Lagrange multiplier, controls the tradeoff between compression and relevance. The solution to this constrained optimization problem has yielded various iterative algorithms that converge to a reduced representation \(\tilde{X}\), given \(p(x,y)\) and \(\beta\) [12]. We choose the sequential optimization algorithm (sIB), as we want a fixed number of hard clusters as output. We use the "IBA-1.0: Matlab Code for Information Bottleneck Clustering Algorithms" (N. Slonim, http://www.cs.huji.ac.il/~noam, 2003).

The input consists of the joint distribution \(p(x,y)\), the tradeoff parameter \(\beta\) and the number of clusters \(M = |\tilde{X}|\). During initialization, the algorithm creates a random partition \(\tilde{X}\), i.e. each element \(x \in X\) is randomly assigned to one of the \(M\) clusters \(\tilde{X}\). Afterwards, the algorithm enters an iteration loop. At each iteration step, it cycles through all \(x \in X\) and tries to assign them to a different cluster \(\tilde{X}\) in order to increase the IB functional:

\[
L_{\text{max}} = I(\tilde{X};Y) - \beta^{-1}I(\tilde{X};X).
\]  

(3)

This is equivalent to minimization of the functional defined in equation 2 and it is used for consistency with [12]. The algorithm terminates when the partition does not change during one iteration. This is guaranteed because \(L_{\text{max}}\) is always upper bounded by some finite value. To prevent the convergence of the algorithm to a local maximum (i.e., a suboptimal solution), we perform several runs with different initial random partitions [12].

3.1 Application to Cortical Features

The feature tensor \(Z\) represents a discrete set of continuous features \(z_{i_1,i_2,i_3} = Z(i_1,i_2,i_3) \in \mathbb{R}^{F \times R \times S}\). Since each response \(z_{i_1,i_2,i_3}\) is collected over a time frame, it can be interpreted as the average count of an inherent binary event (in the case of a neuron, this would be a spike). We therefore consider each response at a location indexed by \((i_1,i_2,i_3)\), as a binary feature whose number of occurrences in a time interval is represented by \(z_{i_1,i_2,i_3}\).

Let the location of a response be denoted by \(x_i\), where \(i = 1,\ldots,F \times R \times S\), such that \(z_{i_1,i_2,i_3} = z_{x_i}\). The 3-dimensional modulation spectrum (frequency - rate - scale) is divided then into \(F \times R \times S\) bins centered at \((f_{i_1},r_{i_2},s_{i_3})\). Given a training list of \(N\) feature tensors \(Z^{(k)}\) and their corresponding targets \(y^{(k)}\), \(k = 1,\ldots,N\), \(y = 1,2\) (the nonspeech and speech tags, respectively), we can now build a count matrix \(K(x,y)\) which indicates the frequency of occupancy of the \(i\)th discrete subdivision of the modulation spectrum in the presence of a certain target value \(y^{(k)}\).

Normalizing this count matrix such that its elements sum to 1, provides an estimate of the joint distribution \(p(x,y)\), which is all the IB framework requires. We assume that \(N\) is large enough such that the estimate of \(p(x,y)\) is reliable, although it has been reported that satisfactory results were achieved even in cases of extreme undersampling [12].

For the purpose of discrimination, the target variable \(Y\) has only two possible values, \(y_1 = 1\) (nonspeech) and \(y_2 = 2\) (speech). We choose to cluster the features \(X\) into 3 groups,
one composed of features relevant to $y_1$, the second of features relevant to $y_2$, whereas the third cluster includes features less relevant to a specific class. Since this setting already implies a degree of compression, we decided to set $\beta^{-1} = 0$ and concentrate on solutions that maximize the relevant information term only. Let us denote a compressed representation (a reduced feature set) by $\tilde{X}$ and the deterministic mapping obtained by sB algorithm as $p(\tilde{x}|x)$. We discard the cluster $\tilde{X}_j$ whose contribution:

$$C_{l(\tilde{x},y)}(\tilde{X}_j) = \sum_y p(\tilde{x}_j,y) \log \frac{p(\tilde{x}_j,y)}{p(\tilde{x}_j)p(y)} \quad (4)$$

to $I(\tilde{X};Y)$ is minimal, because its features are mostly irrelevant in this case. Therefore, we don’t even have to estimate the responses at these locations of the modulation spectrum (in contrast to the HOSVD approach $[6]$). This implies an important reduction in computational load, still keeping the maximally informative features with respect to the task of speech-nonspeech discrimination. To find out the identity of the remaining two clusters, we compute:

$$p(\tilde{x}_j,y) = \sum_x p(x,y)p(\tilde{x}_j|x) \quad (5)$$

$$p(\tilde{x}) = \sum_y p(\tilde{x}_j,y) \quad (6)$$

$$p(y|\tilde{x}) = \frac{p(\tilde{x}_j,y)}{p(\tilde{x})} \quad (7)$$

The cluster that maximizes the likelihood $p(y_1|\tilde{x})$ contains the most relevant features for $y_1$; the other for $y_2$. We denote, hence, the first cluster as $X_1$ and the latter as $\tilde{X}_2$. The typical pattern (3-dimensional distribution) of features relevant for $y_1$ is given by $p(x|\tilde{x} = \tilde{x}_1)$, while for $y_2$ is given by $p(x|\tilde{x} = \tilde{x}_2)$. According to Bayes rule, these are defined as:

$$p(x|\tilde{x} = \tilde{x}_j) = \frac{p(\tilde{x} = \tilde{x}_j|x)p(x)}{p(\tilde{x} = \tilde{x}_j)} \quad j = 1, 2 \quad (8)$$

Figure 1 presents an example of the relevant modulation spectrum of each sound ensemble, speech and non-speech. On average, strongest speech-relevant modulations are between $1 – 8$ cyc/octave (scale), $-1$ and $2$ Hz (rate), and in the $300 – 600$ Hz frequency range. Knowledge of such compact modulation patterns allows us to classify new incoming sounds based on the similarity of their cortical-like representation (the feature tensor $\mathcal{Z}$) to the typical pattern $p(x|\tilde{x} = \tilde{x}_1)$ or $p(x|\tilde{x} = \tilde{x}_2)$. We assess the similarity (or correlation) of $\mathcal{Z}$ to both patterns by their inner (tensor) product (a compact one dimensional feature). We propose the ratio of these similarity measures, denoted as relevant response ratio:

$$R(\tilde{Z}) = \frac{\langle \tilde{Z}, p(x|\tilde{x} = \tilde{x}_2) \rangle}{\langle \tilde{Z}, p(x|\tilde{x} = \tilde{x}_1) \rangle} \geq \lambda \quad (9)$$

where $\tilde{Z}$ is the normalized feature vector. Large values of $R$ give strong indications toward target $y_2$, small values toward $y_1$. For the purpose of classification a threshold ($\lambda$) has to be defined such that any sound whose corresponding relevant response ratio $R$ is above $\lambda$ is classified as speech, otherwise as nonspeech. We calculate the relevant response ratio $R$ for all training examples and noise conditions. Figure 2 shows the histograms of $R$ computed on speech and non-speech examples. It is worth to note that the histograms form two distinct clusters for every SNR, with a small degree of overlap. Obviously, decision threshold $\lambda$ is highly dependent on the SNR condition under which the features are extracted. This is especially true for low SNR conditions (0dB, -10dB).

3.2 Database and feature extraction

Speech examples were taken from the TIMIT Acoustic-Phonetic Continuous Speech Corpus. Music examples were selected from the authors’ music collection. Animal vocalizations consist of bird sounds $[13]$. The noise examples (taken from Noisex) consist of background speech babble in locations such as restaurants and railway stations, machinery noise and noisy recordings inside cars and planes. Training set consists of 500 speech and 560 non-speech samples. One single frame of 500 ms is extracted from each example, starting at a certain sample offset in order to skip initial periods of silence.

From each of these frames, a feature tensor $\mathcal{Z}$ holding the cortical responses is extracted to train the systems which are based on the same auditory features: System 1 reduces their dimensionality using the HOSVD, and classifies the fi-
nal set of features with SVM [6]. System 2 (the proposed one) defines relevant subsets of auditory features according to IB method, and classifies them with the Relevant Response Ratio and a fixed threshold. Likewise, one feature vector z holding MFCC and ZCR features is extracted from each of these frames to train the 3rd system. This system subsequently uses SVM classification. We train each system in a specific SNR condition chosen such that the expected classification performance is high for a broad range of test conditions: this is 10 dB for systems 1 and 2, and 40 dB for system 3.

Test set consists of 260 speech and 300 non-speech examples. Sentences and speakers in test examples are different from the training examples. Since we want to evaluate the robustness and applicability of the systems under realistic conditions, we construct a benchmark test consisting of a variety of labeled sound signals. Each signal is 30 seconds long, and consists of alternating speech - nonspeech test examples with random length (between 2 and 8 seconds). We create 30 such signals, consisting of alternating speech and music, noise, or animal vocalization events. Each of them is corrupted either by additive white noise, or speech babble, at SNRs of 40, 30, 20, 10, 0, and -10 dB, resulting in 360 test signals.

4. EXPERIMENTAL RESULTS

We evaluate systems performance in terms of the F-measure for each non-speech ensemble (music, noise, or animal vocalizations), noise type and level. The F-measure is a common tool to assess the performance of an information retrieval system based on two quantitative measures, precision P and recall R. The results are presented in Figure 3. Both systems 1 and 2 - which are based on the same auditory features - exhibit equally good performance, with generalization ability to various noise conditions for both types of noise. The performance of the 3rd system, which is based on MFCC and ZCR features, degrades remarkably when corrupted by additive white noise, whereas it exhibits a better generalization ability in the case of additive speech babble.

5. CONCLUSIONS

Classical methods of dimensionality reduction seek the optimal projections to represent the data in a low-dimensional space. Dimensions are discarded based on the relative magnitude of the corresponding singular values, even if these particular dimensions could give a clue for classification. In this paper, an information theoretic approach enables the selection of a reduced set of auditory features which are maximally informative in respect to the target - speech or non-speech in this case. A simple thresholding technique is proposed, built upon these reduced representations. It yields a performance close to state-of-the-art classifiers, such as SVMs, with a significantly reduced computational load. An obvious refinement of the system would be the inclusion of a noise energy measure in order to adapt the decision threshold to the observed SNR (according to Figure 2).

Since we wanted to evaluate the process of feature selection per se, we preferred not to use more complex classifiers in this task. In future work, we could test an unsupervised clustering method for the classification of test examples, using the same sequential optimization routine of the sIB algorithm [12]. The method could also be tailored to the recognition of other speech attributes, such as speech or speaker recognition, based upon other features [11] in addition to the spectro-temporal modulations.
